EXECUTIVE SUMMARY

The 71-year (1915-1985) regional average annual rainfall for the SFWMD is 53 inches, with amounts that range from a minimum of 39 inches in 1956 to a maximum of 77 inches that fell in 1947. The annual amounts are averages of basin rainfall amounts over the entire District area and do not reflect the spatial variability. Between 1915 and 1985, the District received between 45 and 55 inches 55% of the time, and between 40 and 60 inches 80% of the time. Annual rainfall between 1940 and 1960 was extremal. The frequency diagram of District annual rainfall shows the distribution to be asymmetric. Statistical goodness-of-fit tests supported the hypothesis that District annual rainfall followed a logarithmic-normal distribution. The parameters of the distribution were estimated from the data by the method of maximum likelihood, allowing rainfall amounts of stated frequencies to be determined. The 1-in-10-year "dry" and "wet" rainfalls are 44.3 and 62.5 inches, respectively. Based on the results of this study, the 1956 rainfall was between the 1-in-50 and 1-in-100-year event, and the 77 inches recorded in 1947 exceeded the 1-in-200-year event. Several of the basins' wet season rainfall has been consistently below the respective historical averages during the past 10 to 15 years. This trend is evident in annual rainfall to a lesser extent as wet season precipitation accounts for approximately two-thirds of annual rainfall District-wide. Graphic information that relates District-wide and individual basin rainfall magnitude and frequency appears in this report. Also, a mainframe computer procedure has been developed by the author which will compute rainfall magnitude and frequency for any sequence of months, for any basin. Annotated examples of the interactive procedure appear in the Appendix.

INTRODUCTION

The objective of this study is to present historical wet season, dry season, and annual rainfall data from the hydrologic basins which comprise the South Florida Water Management District in an informative manner, and to characterize each distribution by statistical inferences in order to determine the functional relationships between rainfall magnitude and frequency. Data from a network of rainfall gaging stations were used in this analysis to determine wet season (June through October), dry season (November through May), and calendar year annual rainfall amounts from twelve hydrologic basins. Annual basin values were area-weighted to compute estimates of District annual rainfall from 1963 to 1985. Estimates prior to 1963 could not be computed in this manner because of missing data in the WCA system and other basins. Statistical techniques were used to provide estimates of missing basin values which were then combined with the historical data to estimate District annual rainfall from 1915 to 1962. A goodness-of-fit procedure was used to test the hypothesis that District annual rainfall is a random variable with an underlying probability distribution. If true, a useful relationship between District annual rainfall magnitude and frequency can be established.

The South Florida Water Management District contains twelve basins whose boundaries are primarily hydrologic in nature. Figure 1 shows the location of each of these basins within the SFWMD. Upper Kissimmee River is the northernmost basin. It contains the Upper Kissimmee chain of lakes and extends southward to the primary outlet structure of Lake Kissimmee, S-65. The Kissimmee River basin extends from S-65 south to Lake Okeechobee and is bounded by Martin County to the east. The Upper East Coast basin is comprised of Martin and St. Lucie Counties. Similarly, the Lower East Coast basin consists of Palm Beach, Broward, and Dade Counties, except for the Everglades National Park, Everglades Agricultural Area, and the Water Conservation Area system, each of which are basins in their own right. Fisheating Creek is one of the true hydrologic basins, lying northwest of Lake Okeechobee and between the Kissimmee and Caloosahatchee River systems. The Lower West Coast forms the largest of the twelve basins. It includes most of Lee, Collier, and Hendry Counties, and, in area, accounts for almost one third of the SFWMD. Although technically not a basin by definition, Lake Okeechobee is so considered because of its unique rainfall characteristics. Rainfall data for all basins have been compiled through 1985, although the basins' periods of record vary from 23 to 71 years. Table 1 shows basic data for each basin, and Figure 2 illustrates the relative size of each basin. Appendix A contains a listing by basin of the raingages used in this report and an accompanying location map. Appendix B contains rainfall data used in this report; period-of-record monthly, wet season, and dry season totals are given for each basin.

HISTORICAL RAINFALL

A. Basin Wet- and Dry-Season Rainfall.

It is worthy to analyze seasonal rainfall in addition to annual rainfall; the effects of two distinct meteorologic regimes (wet season precipitation resulting predominantly from convective and tropical storms, and dry season rainfall coming primarily from frontal systems) can be studied separately. Typically, the months from June to September are classified as "wet" months, and November through April are "dry" months. May and October are transitional months, having precipitation resulting from both wet and dry season regimes. For the purpose of analysis, the wet season in this report begins June 1 and continues through October 30. The dry season begins November 1 and ends May 31 of the following year. A dry season is referred to by the year that contains the months of January through May. For example, dry season 1987 begins November 1, 1986 and ends May 31, 1987.

A *histogram* of rainfall data gives a graphical description of its central value and variability. It is constructed by first partitioning, or discretizing, the range of values into intervals, then counting the number of observations within each interval. A series of vertical bars is then constructed with the bar heights being proportional to the number of observations in the corresponding intervals. As the number of intervals increases (meaning narrower interval widths), the number of observations within each interval decreases, and vice versa. A histogram with interval widths either too wide or too narrow will not effectively display the previously mentioned characteristics of the data. An empirical formula has been developed by Sturges to aid in the selection of an optimal interval width for a given sample of observations:

$$w = \frac{r}{[1 + 3.32log(n)]}$$

where w equals the optimal interval width, r equals the range of the data (the difference between the maximum and minimum value), and n equals the number of observations (sample size). For example, for Upper East Coast wet season rainfall, the maximum and minimum amounts are 44.8 and 18.6 inches, respectively. For a period of 71 years, the interval width computed from equation (1) is (44.8-18.6)/[1+3.32log(71)] or 3.7 inches. Here, a convenient interval width of 5 inches was selected. Similar calculations were made for all basins and, in order to present more uniform results, an interval width of 5 inches was chosen for all histograms in this report. Regardless of interval width, however, some information is lost by discretizing a continuous variable.

Wet- and dry-season rainfall histograms for each basin are presented in Figures 3 through 14. The horizontal axes are identical to facilitate comparison of seasonal rainfall among basins as well as to show the comparison between a basin's wet- and dry-season precipitation. The vertical scales are not uniform, however, as the magnitude of individual bars is not as important as their relative size when making inferences from histograms.

Most of the basins' wet-season histograms (with the exception of Water Conservation Area 1) exhibit a "tighter" distribution than their dry-season counterparts. For wet-season histograms, the interval containing the greatest number of observations is markedly higher than its neighbors, whereas the dry-season histogram peaks are flatter (and wider), indicating a greater variance about the central values.

On the average, the Lower East Coast basin receives the greatest amount of rainfall. From its wet-season histogram (Figure 8a), the LEC basin receives between 30 and 40 inches of rainfall over half of the time during the wet season, and less than 30 inches only 15 percent of the time. The outlier in the interval marked "greater than 60 inches" occurred in 1947 when 69 inches was recorded. This was due in part to the September hurricane that crossed the Florida coast near Ft. Lauderdale. Most of the histograms do not appear to be symmetric about their central values. This asymmetry or skewness will be reflected in the later selection of probability distributions.

Figures 15 through 26 show, in bar-graph form, historical wet- and dry-season rainfall from each basin expressed as a deviation from the corresponding mean rainfall. These graphs are not histograms, and have a time scale on the horizontal axis. Mean dry-season rainfall does not vary from basin to basin as much as mean wet season rainfall. Average dry-season rainfall is about 18 inches except for Water Conservation Area 1 (15 inches) and the Lower West Coast Basin (22 inches). Mean wet season rainfall from four basins (EAA, ENP, LEC, and LWC) is centered around 38 inches, while the remaining eight basins' mean wet-season rainfall centers around 32 inches.

There appears to be little correlation between successive wet- and dry-season rainfall. In other words, a particular wet-season rainfall amount gives little or no indication of what the subsequent dry-season rainfall may be, and vice versa. This observation supports the idea that the wet- and dry-season rainfall processes or "driving-forces" are somewhat independent.

Since the early 1970's, most of the basins have consistently received wet season rainfall amounts well below their respective period of record averages, with exceptions to the Everglades National Park, Lower West Coast, and Upper East Coast basins. The Fisheating Creek and Kissimmee River basins each received below-normal wet season amounts in eleven consecutive years beginning in 1975. The Lower East Coast basin has received below-normal rainfall in thirteen of the past sixteen wet seasons. No similar trends are evident with dry season rainfall. All of these graphs have the same range of rainfall values on the vertical axis (10 - 60 inches) in order to facilitate comparisons. The few observations that exceeded the maximum value on the vertical axis are denoted by an asterisk (*) and the actual rainfall amount. Values that could not be computed because of missing data are denoted with the symbol I about the horizontal axis.

B. Basin Annual Rainfall

Calendar-year annual rainfall from each of the basins was analyzed in a similar manner. The histogram ordinates were re-scaled by dividing each bar by the total number of observations for each basin. Thus, the frequency of rainfall within a particular interval is expressed as a percentage of time rather than a number of occurrences. The basins' rainfall characteristics are more easily compared in this manner, and this transformation represents the next step toward fitting probability distributions to the data, a technique to be presented later. Figures 27 through 38 on the following pages show the histograms for all basins.

Most of the basins' annual rainfall appear to be asymmetric about their respective central values. In Figure 27, the Everglades Agricultural Area interval with the highest relative frequency (the mode) is that between 55 and 60 inches. The observations are not distributed symmetrically about this interval; amounts less than 55 inches are received about 60% of the time while amounts greater than 60 inches occur only 15% of the time. The Everglades National Park (Figure 28) has the opposite appearance; annual rainfall less than 50 inches occurs roughly 20% of the time and amounts greater than 55 inches occur more than half of the time. Distributions which have this asymmetry about their central value exhibit *skewness*. Those having greater variability and frequency below the central value (like the ENP) have positive skewness. Conversely, negative skewness is characterized by a distribution with greater variability and frequency above the central value (like the EAA and Fisheating Creek basins). Annual rainfall over Lake Okeechobee possesses a distribution unique to, and is significantly less than, those from the surrounding basins. Annual rainfall amounts ranging from 35 to 55 inches appear to be equally likely, but amounts outside of this range occur only 10% of the time.

These figures present historical rainfall data in an informative and useful way. Rainfall characteristics are effectively displayed and are easily compared with those from other basins. They also serve as the first step in the statistical analysis of rainfall as a random variable. However, due to the subjective manner in which histograms are constructed, only qualitative inferences should be made from them. Upon successful completion of the analysis more quantitative information may be extracted from the historical data.

Figures 39 through 50 illustrate annual rainfall amounts with respect to the basin means. They indicate that for the past fifteen years, most basins have generally received below-normal annual rainfall. This is most evident in the Upper Kissimmee, Kissimmee River, Fisheating Creek, and Lower East Coast basins. Exceptions occurred in 1982 and in 1983. Trends in annual rainfall are somewhat similar to those evidenced in the wet season figures, since approximately two-thirds of annual precipitation is received during the wet season months. All twelve basins received above-normal rainfall in calendar year 1983, and all but the Upper Kissimmee and Water Conservation Area 2 basins received above-normal rainfall in 1982.

C. District Annual Rainfall

An index of regional rainfall is often more useful than a set of individual basin values. Although it does not reflect the variance within the region, it is a single measure which can be analyzed in a similar manner. District Annual Rainfall (DAR) is computed as an area-weighted average of the twelve basins' annual rainfall. It can be expressed as:

$$DAR = \frac{\sum_{i=1}^{12} R_i A_i}{\sum_{i=1}^{12} A_i} \qquad (2)$$

where R and A are rainfall-depth (inches) and area values (square miles), respectively. The subscript refers to the values being basin-specific. DAR has the same units as R. Conceptually, DAR is the single value of rainfall depth that, when multiplied by the area of the entire District, will yield the same volume of rainfall (rainfall depth x area = rainfall volume) as the sum of the 12 individual basin rainfall volumes. This can be expressed by multiplying both sides of equation (2) by the total area:

$$Volume\ of\ Rainfall =$$

$$DAR \cdot \left(\sum_{i=1}^{12} A_i\right) = \sum_{i=1}^{12} (R_i A_i) \qquad (3)$$

DAR is a characteristic rainfall depth of the District as a whole, and does not give information about the variability of rainfall from basin to basin. It is possible for several basins to receive abnormally high or low rainfall for a given year when DAR is near normal. DAR can be thought of as a linear combination of the basins' annual rainfall. The general expression for a linear combination is:

$$Y = a_1 X_1 + a_2 X_2 + \ldots + a_n X_n \qquad (4)$$

Equation 2 can be written in this form:

$$DAR = \frac{A_1}{\sum_{i=1}^{12} A_i} R_1 + \frac{A_2}{\sum_{i=1}^{12} A_i} R_2 + \ldots + \frac{A_{12}}{\sum_{i=1}^{12} A_i} R_{12} \qquad (5)$$

From the percentages given in Figure 2, DAR is computed as:

$$(.058)R_{EAA} + (.157)R_{ENP} + \ldots + (.058)R_{WC3} \qquad (6)$$

1. Historical Data.

Table 2 lists period-of-record annual rainfall for all 12 basins as well as DAR for years in which annual rainfall data from all 12 basins was available (1963-1985). A record is defined as the set of basin annual rainfall values for a given year. A complete record is one for which values for all 12 basins are available. Thus, DAR may be computed from complete records only, for the period of 1963 to 1985. The histogram of DAR values from 1963 to 1985 is shown in Figure 51. It shows that eight observations were between 45 and 50 inches of rainfall, more than any other interval. Seventy percent of the observations were between 45 and 55 inches. Six observations were greater than 55 inches, while only one year received less than 45 inches. This indicates that the distribution of DAR may be asymmetric about its central value.

The inferences made from this sample of DAR values are limited because of the small sample size (23 years). Estimates of missing basin annual rainfall data via correlation and regression can be used to extend all basins' period of record to seventy-one years (1915-1985), allowing DAR to be computed for this entire period. A histogram similar to Figure 51 can then be constructed, and inferences from this histogram can be made with greater confidence.

2. Extended Period of Record.

This approach uses estimates of missing basin annual rainfall values from linear regression in order that DAR values may be computed for the 71 year period 1915 to 1985. The basin rainfall values are computed as weighted averages of amounts recorded at raingages, using available historical data. Several combinations of raingages may have been used to estimate monthly rainfall values for a particular basin. This is because raingages occasionally malfunction, they frequently are discontinued, and new ones are often added. A raingage network was established in 1981 in order to compute basin rainfall values in a more consistent manner. Missing values in Table 2 are a result of insufficient historical raingage data. Consequently, estimates of District annual rainfall could not be made in years which contained missing basin values. Annual rainfall from basins with missing values was correlated with annual rainfall from a long-term raingage station in order to determine the strength of a linear relationship. If they were highly correlated, values

from the long-term raingage(s) would be used to estimate basin annual rainfall for missing years by using the regression equation. If no raingage values were available for a missing year, or had no valid relationship between raingage- and basin-annual rainfall been found, a regression estimate using an adjacent hydrologic basin as the next-best predictor was used.

Table 3 includes the results of the correlation and regression analyses for the eight basins with missing values. The stair-step line separates the non-missing basin annual rainfall values from those that used a surrogate measure. The shaded values were estimated by raingage regression equations, and values not shaded are estimates from adjacent basin regression equations, as previously stated. The computed DAR values for the 71-year period of record (1915-1985) are also shown. A histogram of these data is shown in Figure 52. The histogram from Figure 51 is superimposed to illustrate the frequency distribution enhancement made by increasing the sample size from 23 to 71. The 71-year histogram is also slightly skewed, and the right half of the histogram has more definition. The maximum value of 77 inches occurred in 1947. During this year, the Lower East Coast basin received 103 inches, more than 40 inches above its normal. Figure 53 shows, for each year between 1915 and 1985, DAR with respect to the 71-year average (mean). It shows that annual rainfall between 1940 and 1960 was extremal, and that a cyclical trend was evident after 1940, with wetter- and drier-than-normal annual rainfall occurring consecutively (on the average in 2 and 3 years, respectively).

The mathematical model used to describe the relationship between basin and predictor (gage or adjacent basin) annual rainfall is written as:

$$Y_i = \alpha + \beta X_i + \varepsilon \qquad (7)$$

where α (intercept) and β (slope) are parameters to be estimated by linear regression, X_i is the predictor annual rainfall, (assumed independent variable) ε is a random component or residual, and Y_i is the observed basin annual rainfall. The regression parameters are estimated from paired observations of basin and gage rainfall (years in which both basin and gage rainfall data are available). Values of gage rainfall from years in which the basin value is missing are used *after* the regression model has been developed, and do not contribute to the estimation of the least-squares linear regression parameters. Equation 8 below is used to compute the estimates of missing basin annual rainfall:

$$\hat{Y} = \alpha + \beta X \qquad (8)$$

The basic assumptions of linear regression are:

(1) the independent variable (X) is treated as errorless, and
(2) the residuals (ε) are independent, normally distributedwith zero mean, and have variance that does not dependon X (constant variance).

The degree of accuracy of these estimates is determined a) by how seriously the inherent regression assumptions are violated and b) by the descriptive statistics such as the coefficient of determination and the standard error of the estimates. Serious departures from the assumptions stated in (2) are detected by examining scatterplots of residuals versus the independent variable and predicted values. Also, a check for residual autocorrelation (time-dependence) is made by examining the sequential plot of residuals. The coefficient of determination, or r-squared (r^2), is a measure of the strength of a linear relationship. Values of r^2 range from 0 to 1, indicating the percentage of the total variation in Y that is explained by X. An r^2 value of 1 indicates a perfect linear relationship. The standard error of the estimate is used to evaluate the accuracy of prediction and is the "average" error in predicting Y from X. It has units of inches. Without a predictor variable and regression model, missing values are best estimated by the mean. The corresponding average error from using the mean as an estimate is its standard deviation. The standard error of the estimate is lower than the standard deviation because some of the variability has been explained by the predictor variable. Good regression models have a standard error much lower than the standard deviation, while poor models exhibit little reduction in uncertainty.

Coefficients of determination ranged from a high of 80% for Lake Okeechobee to 17% for Fisheating Creek. Similarly, the average error in prediction of Lake Okeechobee annual rainfall was reduced to 3.5 inches (the standard error) from 7.7 inches (the standard deviation) by using the regression model in lieu of the mean; that for Fisheating Creek was only reduced to 8.1 inches from 8.8 inches.

ESTIMATON OF DISTRICT ANNUAL RAINFALL PROBABILITY DISTRIBUTION

As mentioned previously, there are limitations to the discretization of DAR. Until now, no assumptions have been made regarding DAR having an underlying theoretical probability distribution. If this assumption can be validated, DAR is treated as a continuous random variable rather than a discrete one. Many hydrologic phenomena are assumed to follow a theoretical probability distribution. The Water Resources Council recommends the Log-Pearson Type III distribution for defining annual flood series[1] and the Gumbel (double negative exponential) distribution has been considered appropriate for defining drought events. The normal, or Gaussian distribution describes many hydrologic processes that are subject to random and independent variations. It has a wide application in dealing with transformed data that subsequently follow the normal distribution. In the log-normal distribution, for example, frequencies will not follow the normal distribution, but their logarithms follow a normal distribution[2]. The logarithmic normal distribution is useful in defining many hydrologic random variables where the values of the variate are the result of underlying multiplicative factors, and are known to be strictly positive[3], and has been previously used to define rainfall. In this analysis, the data were fitted to two distributions: normal and log-normal.

A Kolmogorov-Smirnov (K-S) goodness of fit test was performed on each basin's wet season, dry season, and annual rainfall, as well as the 23 years of DAR, to determine the relative appropriateness of the two distributions. Appendix E lists the K-S significance levels with a brief interpretation of the results. Eight of the 12 basins' annual rainfall were judged to be more log-normally distributed than normally distributed, as was District annual rainfall[4]. The acceptance of an underlying distribution assumes the observations are random and independent. Though the assumption of independence theoretically may be more reasonable for seasonal rainfall than for annual rainfall because the observations do not form a continuum, both wet season and annual rainfall plotted versus time (Figures 15 through 26 and 39 through 50) show cyclical trends and characteristics of time-dependence. This analysis, however, is robust, in that small departures from the basic assumptions will not seriously affect the validity of the results.

The log-normal distribution is described by two parameters, the mean λ (lambda) and the variance ζ^2 (zeta squared). These population parameters must be estimated by sample statistics calculated from the historical data. Estimates of these parameters are denoted as $\hat{\lambda}$ ("lambda hat") and $\hat{\zeta}^2$, respectively. There are two commonly used methods of parameter estimation: the method of maximum likelihood and the method of moments. The method of maximum likelihood computes the statistics as follows:

$$\hat{\lambda} = \frac{1}{n} \sum_{i=1}^{n} ln(x_i) \quad (9)$$

$$\hat{\zeta}^2 = \frac{1}{(n-1)} \sum_{i=1}^{n} [ln(x_i) - \hat{\lambda}]^2 \quad (10)$$

where n is the sample size and ln (x_i) is the natural logarithm (base e) of the i^{th} observation. The method of moments relates the distribution parameter estimates to the sample moments (in this instance, the first two moments, the mean and the variance). The log-normal parameters are estimated by:

$$\hat{\lambda} = ln(\bar{X}) - \frac{1}{2}s^2 \quad (11)$$

and

$$\hat{\zeta}^2 = ln(1 + \frac{s^2}{\bar{X}^2}) \quad (12)$$

A study comparing the methods of the log-normal distribution parameter estimation[5] favors the use of the method of maximum likelihood based on superior performance for sample sizes greater than twenty; the method of maximum likelihood is used in this report.

[5] J. R. Stedinger, "Fitting Log-Normal Distributions to Hydrologic Data," Water Resources Research, Vol. 16, No. 3, pp. 481-490, June 1980.

Log-normal distribution parameters were estimated for DAR based on the 71-year period, 1915-1985.Parameter estimates from the better-fitting distribution were made for wet season, dry season, and annual rainfall from each of the basins. Though the use of estimates of missing basin values was acceptable for computing additional DAR values, their use is not warranted in the analysis of basin rainfall *per se*. Table 4 lists the median and mean annual rainfalls for each basin and the District. The parameter λ is related to the median annual rainfall, X_m (defined as the rainfall having 50% probability of exceedance in any given year) by: $X_m = e^{\lambda}$.

Table 4. Basin Rainfall and DAR Statistics

Basin	Median Xm (inches)	Mean $\bar{X}$ (inches)
EAA	52.2	52.9

WCA-1	48.2	48.6
WCA-2	46.7	47.0
WCA-3	44.2	44.6
DAR	52.6	52.8

The sample statistics $\hat{\lambda}$ and $\hat{\zeta}$ are sufficient to describe the log-normally distributed random variable, District annual rainfall. That is, no information is lost from the sample by summarizing the data in terms of $\hat{\lambda}$ and $\hat{\zeta}$. These statistics also define the probability distribution of DAR. This is represented by its *probability density function* (PDF), and is shown in Figure 54. The histograms in Figures 51 and 52 are similar to, and in fact, a discrete approximation of, the PDF in Figure 54. In order to make a direct comparison to the PDF (giving a visual goodness of fit of the data to the theoretical distribution), the vertical axis on the histogram is rescaled to produce a *frequency diagram*. This is accomplished by dividing each ordinate by the total area of the histogram. For example, the frequency diagram ordinate for 45 to 50 inches is obtained by taking the corresponding histogram ordinate (19 occurrences), and dividing by the total histogram area (71 occurrences x 5 inches). The resultant frequency, 0.054/inch may be compared with the PDF evaluated at 47.5 inches (the interval midpoint), which is approximately 0.048/inch. Probabilities of occurrence are associated with intervals, and not specific values. For example, the probability of DAR being between 60 and 65 inches in any given year is defined as the area under the PDF between 60 and 65 inches. From this definition and by making the interval width smaller and smaller, it follows that the probability of receiving exactly 62.5 inches (or any other single value) of rainfall is zero.

An easier graphical tool to determine probabilities is the cumulative distribution function (CDF). The CDF of District annual rainfall is shown in Figure 55. Mathematically, the CDF is the integral of the PDF. The CDF yields the probability that DAR will be less than the stated rainfall in any year. This can be written as:

$$F(X) = P(X < x)$$

Similarly,

$$1 - F(X) = P(X \geq x),$$

and this gives the probability that DAR will equal or exceed the stated rainfall in any given year. Both graphs appear in Figure 55. The examples to follow illustrate the utility of Figure 55 in determining DAR magnitude and frequency.

Q: What is the probability of the District receiving between 55 and 60 inches of rainfall in any one year?

A: This probability statement is written $P(55 \leq x < 60)$, and is computed as the difference between the CDF values for 55 and 60 inches: F(60) - F(55). Since F(60) = 0.85 and F(55) = 0.68, $P(55 < X < 60)$ = 0.17 or 17%.

Q: What is the 1-in-10-year "dry" or below-normal annual rainfall?

A: The 1-in-10-year dry annual rainfall is defined as having probability of 1/10 receiving that amount of rainfall or less in any year. That is, the 1-in-10-year dry rainfall is experienced on the average once in ten years. It is determined by locating F(X) = 0.10 and reading the corresponding CDF value. From Figure 55, the 10-year dry annual rainfall is approximately 44 inches.

Figure 54.

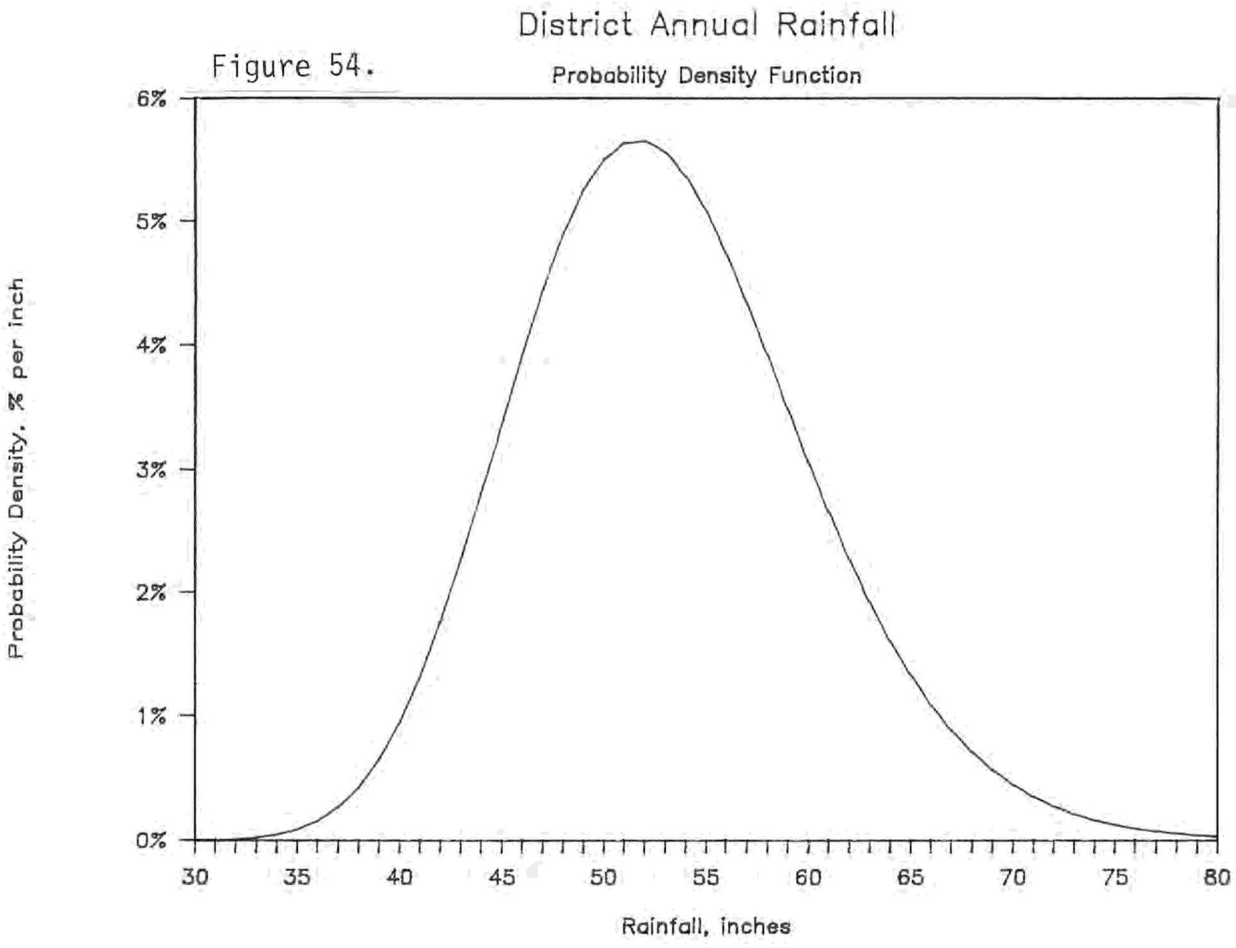

Figure 55.

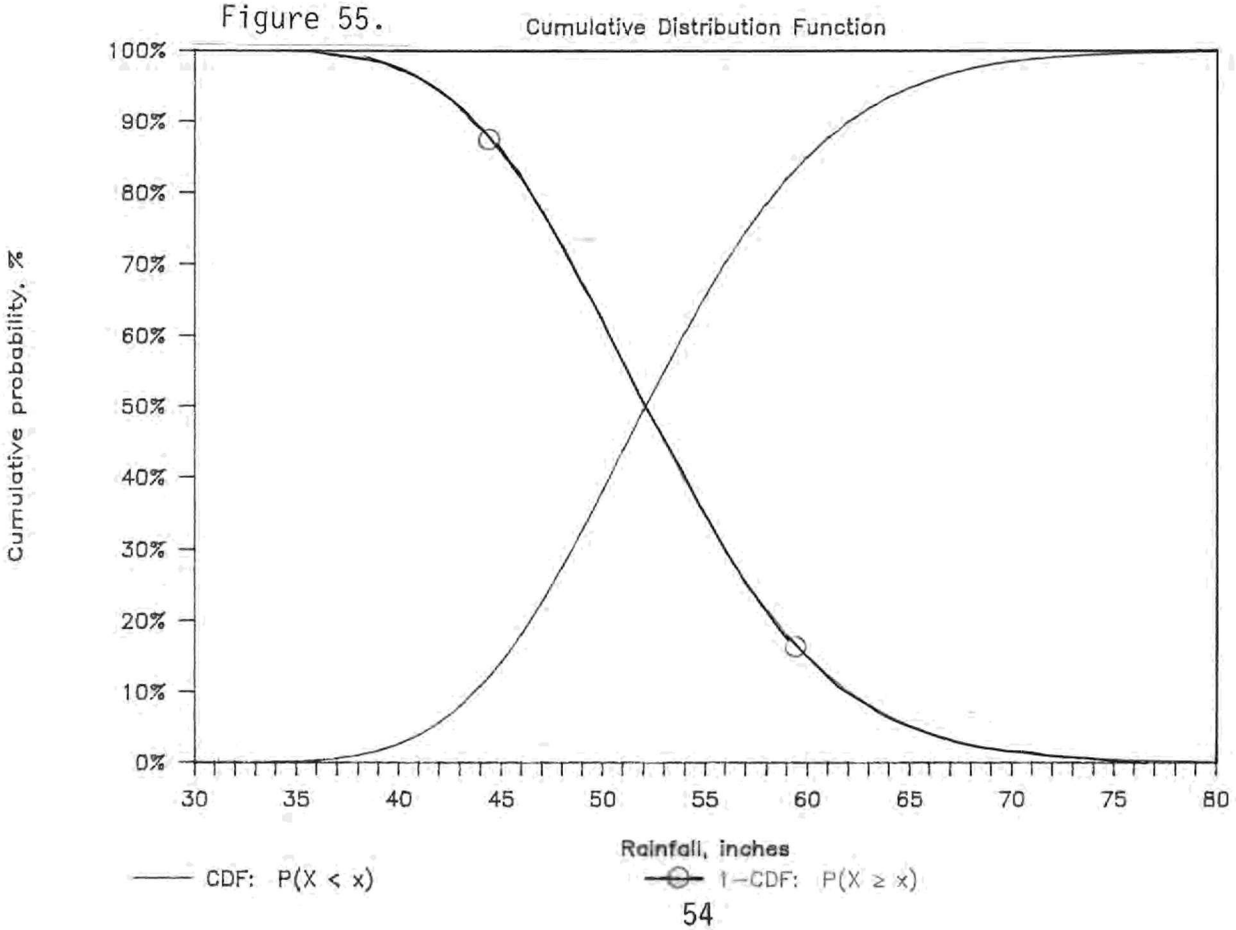

Q: What is the 1-in-10-year "wet" annual rainfall?

A: This is similarly defined as the rainfall having probability of exceedance of 10% in any given year. The "1-CDF" curve is read as 62.5 inches.

Note that where the two curves in Figure 55 intersect is the District median annual rainfall (X_m), 52.6 inches.

Table 5. Historical versus Log-Normal DAR Frequency

Rainfall Interval (inches)	Number of Occurrences in 71 Years	
	Historical	Log-Normal
<30	0	0
30-35	0	0
35-40	2	2
40-45	6	7
45-50	19	18
50-55	19	20
55-60	13	14
60-65	8	8
65-70	3	3
70-75	0	0
75-80	1	0
>80	0	0
Totals	71	71

The procedure in the above examples were used to construct a log-normal histogram to compare the theoretical distribution with the historical data. Table 5 lists the ordinates of both histograms as they appear in Figure 56. Histograms were compared in lieu of frequency diagrams because the ordinate units are more easily interpreted. Figure 56 shows how well the log-normal distribution reproduced the historical data. As stated previously, the K-S test was used to assess the validity of the assumed underlying distribution. Similar PDF and CDF graphs were developed for the 12 hydrologic basins (wet season, dry season, and annual rainfall) and are in Appendix C.

Table 6 lists DAR for selected return periods. A return period (in years) is defined as the reciprocal of the exceedance frequency. Thus the 1-in-50-year DAR has probability of exceedance of 1/50 or 0.02. It is also referred to as the "2%-chance" DAR. These values were computed because the extreme values are not easily read from Figure 55. The term "exceedance" is used loosely here because of the dual meaning of an "n-year" annual rainfall. "Exceedance" is used here to mean to experience a more extreme event (high or low).The degree of certainty or confidence associated with an estimate obtained from a probability distribution is dependent on both the associated exceedance frequency and the sample size. For a given sample, there is less certainty about extreme events than frequently occurring ones. More intuitively, the degree of confidence associated with an estimate of any event increases with more observations (larger sample size). Confidence intervals are often reported in lieu of point estimates, especially with unusually small sample sizes and/or rare events.

Table 6. District Annual Rainfall Magnitude and Frequency

Return Period (years)	Exceedance Frequency (years-1)	DAR (inches)	
		Dry	Wet
2	0.5	52.6	52.6
5	0.2	47.0	58.9
10	0.1	44.3	62.5
25	0.04	41.5	66.6
50	0.02	39.9	69.4
100	0.01	38.4	72.1
200	0.005	37.2	74.5

Often, the CDF is plotted on probability paper with axes scaled such that it appears as a straight line. Since the DAR values are log-normally distributed (their logarithms are normally distributed), the rainfall scale on the vertical axis is logarithmic and the frequency scale is linear in the transformed standard normal variate, z (the number of standard

Log-normal

deviations away from the mean a particular value lies). It is computed by:

$$z = \frac{[ln(x_i) - \hat{\lambda}]}{\hat{\zeta}} \quad (13)$$

and is dimensionless. This transformation form ln x_i to z allows a table of standard normal probability to be used to determine exceedance probabilities. Figure 57 shows this plot with exceedance and non-exceedance probabilities (expressed as percentages) on the upper and lower horizontal axis, respectively. Appendix D contains the wet season, dry season, and annual rainfall magnitude and frequency graphs for each basin. Table 7 lists the 2-, 10-, and 100-year wet (above-average) and dry (below-average) basin amounts for the wet season, dry season, and annual rainfall. Note that as in Table 6, the 2-year wet and dry amounts are equivalent; the 2-year rainfall is average rainfall.

A computer procedure has been developed on the SFWMD's CDC mainframe that analyzes sequential monthly rainfall from any of the basins. Results from the procedure include rainfall magnitude and frequency computed from the basin and span of months specified by the user. The K-S goodness of fit test is used to select the better of the two distributions (normal or log-normal). Simple statistics are reported (means and standard deviations), as are rainfall amounts above and below normal having return periods of 2, 5, 10, 20, 50, and 100 years. Examples of the interactive procedure appear in Appendix F, along with a listing of the programs which comprise the procedure.

RAINFALL ANALYSIS OF HYDROLOGIC BASINS PRESENTED IN MONTHLY OPERATIONS REPORT

The Department of Resource Operations in their monthly summary of meteorologic, hydrologic, and hydraulic conditions has subdivided most of the SFWMD into reporting areas that are somewhat different from the planning area basins that were analyzed. Figure 58 identifies the nine basins which comprise the entire District except for the Everglades National Park. The Upper Kissimmee, Lower Kissimmee, Ft. Pierce area (Upper East Coast), Everglades Agricultural Area, and Lower East Coast basins are similar to the corresponding planning area basins. The Lake Okeechobee reporting area includes the Taylor Creek/Nubbin Slough, and Indian Prairie watersheds. The conservation areas have been combined with a portion of Hendry County to form one reporting area. The Caloosahatchee and Collier County basins complete the reporting areas. These reporting areas were chosen in most cases on the basis of drainage patterns and coincide with the District hydrologic basins.

The purpose of analyzing reporting-area rainfall is to be able to provide information about basins defined in this manner. The same basic rainfall data are used regardless of how the SFWMD is subdivided. That is the analysis of, and conclusions drawn, about SFWMD total rainfall is independent of how basins are defined. For this reason, results from these reporting areas will not be combined for further analyses. Because of the noted similarities between many of the reporting- and planning-areas, only the rainfall from the Water Conservation Areas, Collier County, Caloosahatchee, and Lake Okeechobee reporting areas will be analyzed.

Figures 59-62 show the historical wet- and dry-season rainfalls with respect to the period-of-record means. Because of the lack of an adequate raingage network in Hendry County that is part of the water conservation reporting area, many annual and seasonal values were unable to be estimated. Statistical rainfall analysis is not warranted in this case for a lack of sufficient data (see Figure 62). Figures 63-66 show similar historical annual rainfall for the same reporting areas. The wet-season, dry-season, and annual rainfall magnitude and frequency plots for the Collier County, Caloosahatchee, and Lake Okeechobee reporting areas are in Appendix G.

Appendix E

Kolmogorov-Smirnov Goodness of Fit Test Statistics

Appendix E. Kolmogorov-Smirnov Significance Levels

Basin	Wet Season		Dry Season		Annual	
	Normal	Log Normal	Normal	Log Normal	Normal	Log Normal
Everglades Agricultural Area	**.38**	.11	**.89**	.77	**.88**	.51
Everglades National Park	.31	**.64**	**.94**	.42	.64	**.95**
Fisheating Creek	.74	**.80**	**.59**	.44	**.91**	.76
Kissimmee River	.99	**.996**	**.53**	.33	**.73**	.63
Lower East Coast	.25	**.76**	.77	**.85**	.47	**.84**
Lake Okeechobee	**.92**	.86	**.99**	.63	**.84**	.70
Lower West Coast	.43	**.77**	**.94**	.90	.66	**.95**
Upper East Coast	**.32**	.11	.71	**.90**	.90	**.99**
Upper Kissimmee River	.24	**.59**	.32	**.53**	.73	**.99**
Water Conservation Area 1	**.99**	.96	**.39**	.12	.37	**.55**
Water Conservation Area 2	.87	**.99**	**.98**	.59	.36	**.51**
Water Conservation Area 3	**.97**	.80	**.96**	.68	.88	**.96**

For a significance level of $\alpha = .95$, this means there is a $100(1-\alpha)\%$ or 5% chance that the population does not follow the specified distribution. This does *not* mean that there is a 95% chance that population is normally distributed; there may be other distributions that yield equally high or higher significance levels.
